Appendix B: Deviations from the QAPP

We encountered four significant circumstances which were unanticipated in the QAPP or may be considered deviations from the QAPP. Our rationale for the field decisions and the consequences are discussed in the following subsections.

Inlet clogging and other pump related issues

The initial pump inlet design included a screen in an attempt to exclude debris. However, the relatively fine screen (#40 mesh size, nominal opening 0.42mm) rapidly clogged within about a week of pump startup. Figure 1-B below shows the screened inlet we initially used.

Figure 1-B. Initial stormwater inlet pump screen.

We removed this screen in early March 2017 when it was apparent that little water was capable of flowing through it. Unfortunately, the stormwater inputs to the vault, also included a significant amount of debris (i.e., large amounts of sticks, leaves, and other ligneous plant fibers) which then rapidly clogged the pump inlet and manifold. From March 2017 until April 2017, we used stainless steel dental picks and clean compressed air to remove this debris, but rapid re-clogging of the inlet and distribution tubing necessitated a more permanent solution. We folded a coarse 304 series stainless steel screen with

pre-dilled ~2.38 mm holes into a box around the inlet standpipe. The screen was able to remove most of the plant debris from the stormwater and reduce the frequency of tubing and manifold cleanings to every six months or more. Figures 3-A and 4-A above illustrate our final inlet design. Due to clogging issues, only flow at the beginning of storm events was delivered to mesocosms for the first few months of the project. This was due to the rapid clogging of inlet tubing whenever stormwater (as opposed to baseflow) was in the vault. While the full spectrum of the storm hydrographs was not dosed to the mesocosms for the first 10 weeks of the study, the 120 ml/min stormwater doses were drawn equally from across the entire hydrograph for the remainder of the 25 month study duration (90 weeks).

Sprinkler head clogging

We began the project with ~20 cm sprinkler heads at the termination of each Teflon dosing tube. We constructed the sprinkler heads with the same ¼” Teflon tubing we used for the distribution lines and drilled ~1.5 mm holes approximately 15 mm apart along their periphery to evenly distribute stormwater over the mesocosm surface. However, the sprinkler head holes rapidly clogged with debris and were disconnected from the distribution tubing after about a month. For the remainder of the study (24 months) the ¼” dosing tubing discharged directly to the mesocosms without use of sprinklers or other areal diffusers. We shifted placement of the distribution tubing above the surface of each mesocosm during site maintenance and soil collection, but not in a systematic way. Therefore, in theory, PCBs, other contaminants, or TSS may have been concentrated in a particular section of a mesocosm directly under the dosing tubing. However, the likelihood of this happening substantively enough to effect the study results seems remote to us for several reasons.

First, the area of the 55 gallon barrel mesocosms is relatively small at 0.256 m² (2.76 ft²). Second, the soil cores were collected from three different areas of each mesocosm to account for any spatial heterogeneity in the soil concentrations both vertically and horizontally. Lastly, we frequently observed standing water above the soil surface in the mesocosms during prolonged storm events. This water would infiltrate as evenly as could be expected, likely negating any small localized affects the “drip” from the discharge may have had on the soils immediately underneath.

Flow measurement and sampling discrepancies

Prior to initiation of the project, the peristaltic pump manufacturer indicated that aging of the silicon tubing would likely change the delivered volume over time. To address this issue we installed a Cole-Parmer ultrasonic Doppler continuous flow meter (model number EW-32615-62) with a Cole Parmer transducer (model EW-32615-68) on the 3/8” inlet tubing. Our intent was to divide this continuously measured inlet volume by 12 to derive the volume of stormwater delivered to each mesocosm. Unfortunately, the flow meter was unable to account for the widely varying amount and type of solids associated with stormwater and baseflow. While the mass of suspended solids only varied between 9 to 64 mg/L depending on the influent replicate measurement, solids content in baseflow (which were not analyzed) was likely as low as 0.5 to 3 mg/L. Additionally, based on visual observations, the types of solids in the influent varied widely on a daily basis and between storm events. We weren’t able to quantify these changes as part of this project, but for

instance, there were noticeable seasonal changes in leaf litter volume. The variation in solids concentration, parent material, size fraction etc. changed the calibration and performance of the Doppler flow meter signal from day to day and season to season. Regardless of the actual flow volume, the flow meter would read low on days with cleaner, clearer influents and high on turbulent high volume storm days due to the variable reflectivity of the influent. Because we were unable to calibrate the flow meter across these varying influent conditions, we needed an alternative approach to measure and estimate stormwater doses.

We did not measure variation in the actual volumes delivered by the pumps, which consistently delivered 360 ± 5 mL of influent in three minutes when measured with a 500 mL graduated cylinder (120 mL/min). Because the actual pump rate did not vary substantively, we confirmed that changes seen on the flow meter were an artifact of its design as well as performance in highly variable TSS conditions. As a remedy for the inability to use the flow totalizer functions of the meter, we used the flow meter record as an indication of whether the pumps were on or off. The total number of minutes of pump runtime was multiplied by the confirmed 120 mL/min dosing rate to derive the stormwater dose per mesocosm.

In addition to issues with the totalizer functions, the flow meter cables were vandalized in November 2018. This event disabled all flow and pump monitoring capacity, so we turned the pumps off until early March 2019. Because we did not dose the mesocosms for four months, we did not collect the quarterly BSM sample scheduled to occur at this time. We collected the seventh and final BSM sample about two weeks after the pumps were restarted in early March 2019.

We also experienced an analytical sampling discrepancy during the March 12, 2019 storm sampling event. We inadvertently did not collect an effluent sample from mesocosm #10 during this storm event.

Hydraulic conductivity testing

Our project shared 6 of 12 mesocosms with another concurrent study (Taylor et al. 2016), which in part evaluated hydraulic conductivity over time. Their testing was initially conducted by filling the mesocosms with clean tap water from the bottom using the standpipes visible on the upper right hand side of Figure 2-B below. Saturation of the mesocosms from the bottom via the drain standpipes successfully avoided adding air pockets in the BSM or mulch. Unfortunately, by the second conductivity test (late Spring 2017), it was obvious to us that this procedure also floated organic fines from the compost fraction of the BSM to the surface of the mesocosm just beneath the mulch layer. As water subsequently drained, these fines were compacted and reduced the surficial hydraulic conductivity of the mesocosms to the point where small volumes of stormwater overflowed during subsequent storm events. The overflow volumes were not consistent between mesocosms as the surficial conductivity was not reduced uniformly across all mesocosms. The overflow volumes were not measured, although we estimate they were between 10 and 50 L per mesocosm. Because a little over 13,000 L was dosed to each mesocosms over

25 months, we do not believe this relatively small overflow volume influenced the results or conclusions of the study. The fines that had floated to the surface gradually migrated back into the BSM over a few weeks and we did not record any additional overflow events during the remaining 21 months of the study. Figure 2-B shows some of the mesocosms in a near overflow condition after a rain event in early May 2017.

Figure 2-B. Flooded mesocosms with hydraulic conductivity standpipes shown in the upper right.

PCB Analysis and co-elution changes

Pacific Rim Laboratories performed all of the PCB chemistry analysis for this project. Pacific Rim Laboratories is Washington State Department of Ecology accredited for EPA Method 1668. Method 1668 is a high resolution gas chromatograph mass spectrometer isotope dilution method and considered the most robust and precise for measuring PCB congeners. Dual (parallel) chromatographic columns are used in methods like EPA 1668 to separate PCB compounds based on their molecular structure, which influences how they move through the column packing. Despite this method's high resolution and precision, not all PCB congeners are resolvable on the gas chromatographic columns in use. When two or more congeners are not analytically resolvable from each other they are considered to "co-elute" and their results are reported together. Different gas chromatographic column types will have different combinations of co-eluting congeners. The reported value for co-eluting congeners is a sum of these undifferentiated congeners.

During the PCB analysis for this project and other King County projects using Pacific Rim Laboratories during 2017-2018, we observed that performance of the chromatographic columns used by Pacific Rim had changed. These changes meant that the congeners which co-eluted varied over time and were inconsistent between samples. Following discussions with chemists at Pacific Rim Laboratories we determined that these results were not due to changes in the analytical method, but were the result of changes to the chromatographic column. The column manufacturer had changed the composition of packing material in the column, which then changed their analytical performance and resulted in unanticipated impacts to our projects samples.

The pattern of congener co-elution we observed in study samples were different than those observed in samples analyzed for previous studies conducted by King County and Ecology. While the shift in congener co-elution patterns over time does not invalidate the results and they still meet specifications in EPA method 1668, the unexpected differences made data analysis more challenging and potentially limit data comparability to other projects. For the purposes of this project, we standardized all samples to a common set of co-eluting congeners even if in most cases no congeners in a sample actually co-eluted in that manner. For example, PCB-086, PCB-097, and PCB-117 co-eluted in Column A; PCB-097, PCB-116, and PCB-117 co-eluted in Column B; and PCB-116 and PCB-125 co-eluted in Column C. We combined these differences and summed PCB congeners 086/097/116/117/125 by sample regardless of which column was used for which sample. This resulted in our use of a common set of co-eluting congeners for all samples, although this combination of co-eluting congeners does not match other projects or analyses.

In addition to the issue of differing congener co-elution patterns described above, sample detection limits (SDL) also varied slightly. These relatively small variations were due to matrix and other sample specific interferences. All SDLs were below the maximums specified in EPA Method 1668 and all data were validated according to EPA Region 10 guidelines by an independent third party (Laboratory Data Consultants, Carlsbad, California). Table 1-B lists the co-eluting congeners alongside the minimum and maximum SDLs encountered for both BSM and water.

Table 1-B. Co-eluting PCB congeners along with the range of water and BSM sample specific detection limits.
